

Analysis and Simulation of a Digital Mobile Channel Using Orthogonal Frequency Division Multiplexing

LEONARD J. CIMINI, JR., MEMBER, IEEE

Abstract—This paper discusses the analysis and simulation of a technique for combating the effects of multipath propagation and cochannel interference on a narrow-band digital mobile channel. This system uses the discrete Fourier transform to orthogonally frequency multiplex many narrow subchannels, each signaling at a very low rate, into one high-rate channel. When this technique is used with pilot-based correction, the effects of flat Rayleigh fading can be reduced significantly. An improvement in signal-to-interference ratio of 6 dB can be obtained over the bursty Rayleigh channel. In addition, with each subchannel signaling at a low rate, this technique can provide added protection against delay spread. To enhance the behavior of the technique in a heavily frequency-selective environment, interpolated pilots are used. A frequency offset reference scheme is employed for the pilots to improve protection against cochannel interference.

I. INTRODUCTION

SEVERE multipath propagation, arising from multiple scattering by buildings and other structures in the vicinity of a mobile unit, makes the design of a mobile communication channel very challenging [1]. This scattering produces rapid random amplitude and phase variations in the received signal as the vehicle moves in the multipath field. In addition, the vehicle motion introduces a Doppler shift, which causes a broadening of the signal spectrum. Measurements confirm that the short-term statistics of the resultant signal envelope approximate a Rayleigh distribution.

Multipath fading may also be frequency selective, that is, the complex fading envelope of the received signal at one frequency may be only partially correlated with the received envelope at a different frequency. This decorrelation is due to the difference in propagation time delays associated with the various scattered waves making up the total signal. The spread in arrival times, known as delay spread, causes transmitted data pulses to overlap, resulting in intersymbol interference. In a typical urban environment, a spread of several microseconds and greater can be occasionally expected.

There is an additional impairment in a cellular mobile system. The available radio channels are reused at different locations within the overall cellular service area in order to use the assigned spectrum more efficiently. Thus, mobiles simultaneously using the same channel in different locations interfere with each other. This is termed cochannel interference and is often the dominant impairment.

In addition, there is a long-term variation of the local mean of the received signal, called shadow fading. Shadow fading in a mobile radio environment is caused by large obstacles blocking the transmission path. This impairment is alleviated in cellular systems by using transmitted and received base-station signals at two different geographical locations [1], and will not be discussed in this paper.

Given the harsh mobile environment and the scarcity of

available spectrum, it is desirable to look for channel designs which provide good performance for both speech and data transmission, and which are also bandwidth efficient. The channel designs presented in this paper could accommodate speech or data transmission. For the narrow channel assumed, a low-bit-rate speech coder would be required. For example, a 7.5 kHz channel using the system proposed in this paper can support 8.6 kbits/s. In what follows, the channel will be assumed to be transmitting data symbols.

In a conventional serial data system, the symbols are transmitted sequentially, with the frequency spectrum of each data symbol allowed to occupy the entire available bandwidth. Due to the bursty nature of the Rayleigh channel, several adjacent symbols may be completely destroyed during a fade. To illustrate the severity of the problem, consider the following example. Assume that there is a cochannel interferer with an average power level 17 dB below that of the desired signal. This condition occurs approximately 10 percent of the time in a cellular mobile system. A fade 17 dB below the average level will bury the desired signal in the interference. At a carrier frequency of 850 MHz and a vehicle speed of 60 mph, the average fade duration for a fade 17 dB below the local mean of the desired signal is 0.75 ms [1]. For a data rate of 10 kbits/s, 7 or 8 adjacent bits would be destroyed during such a fade.

In a serial system, higher data rates can be achieved, at the expense of a degradation in performance, by using higher order modulations or, at the expense of increased channel bandwidth, by decreasing the symbol interval. However, delay spread imposes a waiting period that determines when the next pulse can be transmitted. This waiting period requires that the signaling be reduced to a rate much less than the reciprocal of the delay spread to prevent intersymbol interference. Decreasing the symbol interval makes the system more susceptible to delay spread impairments.

A parallel or multiplexed data system offers possibilities for alleviating many of the problems encountered with serial systems. A parallel system is one in which several sequential streams of data are transmitted simultaneously, so that at any instant many data elements are being transmitted. In such a system, the spectrum of an individual data element normally occupies only a small part of the available bandwidth. In a classical parallel data system, the total signal frequency band is divided into N nonoverlapping frequency subchannels. Each subchannel is modulated with a separate symbol and, then, the N subchannels are frequency multiplexed. A more efficient use of bandwidth can be obtained with a parallel system if the spectra of the individual subchannels are permitted to overlap, with specific orthogonality constraints imposed to facilitate separation of the subchannels at the receiver.

A parallel approach has the advantage of spreading out a fade over many symbols. This effectively randomizes the burst errors caused by the Rayleigh fading, so that instead of several adjacent symbols being completely destroyed, many symbols are only slightly distorted. This allows precise reconstruction of a majority of them. A parallel approach has the additional advantage of spreading out the total signaling interval, thereby reducing the sensitivity of the system to delay spread.

Several systems have previously used orthogonal frequency

division multiplexing (OFDM) [3]–[8]. In particular, in the early 1960's, this technique was used in several high-frequency military systems (for example, KINEPLEX [9], ANDEFT [10], KATHRYN [11], [12]), where fast fading was not a problem. Similar modems have found applications in voice bandwidth data communications (for example, [13]) to alleviate the degradations caused by an impulsive noise environment.

In this paper, a parallel system which uses the OFDM technique is described. In Section II an analysis and simulation of the basic system, using pilot-based correction, is presented. In Section III a practical 7.5 kHz channel design is presented, along with a discussion of several of the problems encountered in reliably retrieving the pilots used in the data correction process. Several solutions to these problems are also presented.

This investigation is simplified by the assumption that the sole source of additive signal degradation is cochannel interference—thermal noise is assumed negligible. Man-made environmental noise, such as that caused by automotive ignitions or neon lights, is also ignored. However, these impairments are basically impulsive and their effect should be greatly reduced by this technique.

II. BASIC PRINCIPLES OF OPERATION

A. Orthogonal Frequency Division Multiplexing (OFDM)

When an efficient use of bandwidth is not required, the most effective parallel system uses conventional frequency division multiplexing where the spectra of the different subchannels do not overlap. In such a system, there is sufficient guard space between adjacent subchannels to isolate them at the receiver using conventional filters. A much more efficient use of bandwidth can be obtained with a parallel system if the spectra of the individual subchannels are permitted to overlap. With the addition of coherent detection and the use of subcarrier tones separated by the reciprocal of the signaling element duration (orthogonal tones), independent separation of the multiplexed tones is possible.

Consider the system shown in Fig. 1. The transmitted spec-

tral shape is chosen so that interchannel interference does not occur; that is, the spectra of the individual subchannels are zero at the other subcarrier frequencies. The N serial data elements (spaced by $\Delta t = 1/f_s$ where f_s is the symbol rate) modulate N subcarrier frequencies, which are then frequency division multiplexed. The signaling interval T has been increased to $N\Delta t$, which makes the system less susceptible to delay spread impairments. In addition, the subcarrier frequencies are separated by multiples of $1/T$ so that, with no signal distortion in transmission, the coherent detection of a signal element in any one subchannel of the parallel system gives no output for a received element in any other subchannel. Using a two-dimensional digital modulation format, the data symbols $d(n)$ can be represented as $a(n) + jb(n)$ (where $a(n)$ and $b(n)$ are real sequences representing the in-phase and quadrature components, respectively) and the transmitted waveform can be represented as

$$D(t) = \sum_{n=0}^{N-1} \{a(n) \cos(\omega_n t) + b(n) \sin(\omega_n t)\} \quad (1)$$

where $f_n = f_0 + n\Delta f$ and $\Delta f = 1/N\Delta t$. This expression and the following analyses can be easily extended to include pulse shaping other than the assumed rectangular shape.

Theoretically, M -ary digital modulation schemes using OFDM can achieve a bandwidth efficiency, defined as bit rate per unit bandwidth, of $\log_2 M$ bits/s/Hz. This is easily shown as follows. Given that the symbol rate of the serial data stream is $1/\Delta t$, the bit rate for a corresponding M -ary system is $\log_2 M/\Delta t$. Each subchannel, however, transmits at a much lower rate, $\log_2 M/(N\Delta t)$. The total bandwidth of the OFDM system is

$$B = f_{N-1} - f_0 + 2\delta \quad (2)$$

where f_n is the n th subcarrier and δ is the one-sided bandwidth of the subchannel (where the bandwidth is considered as the

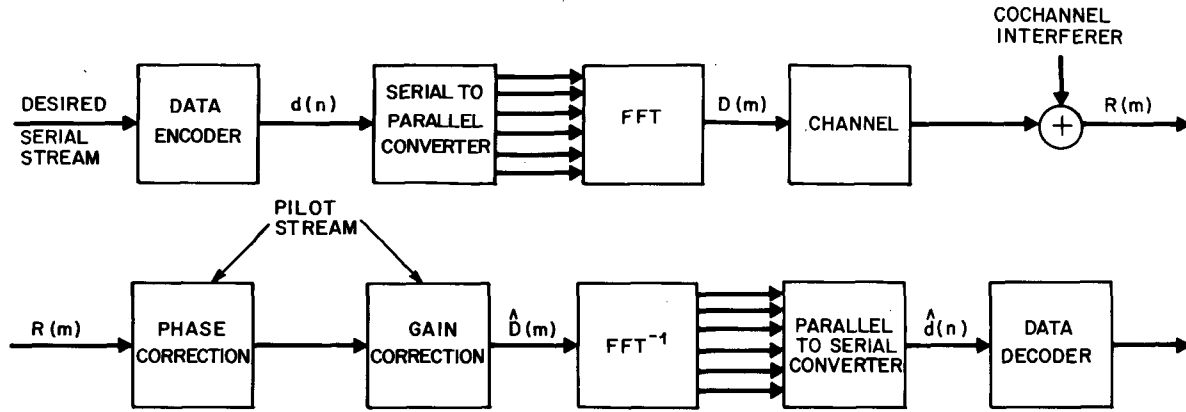

Fig. 2. OFDM system implemented with an FFT.

distance to the first null). The subcarriers are uniformly spaced so that $f_{N-1} - f_0 = (N-1)\Delta f$. Since $\Delta f = 1/N\Delta t$ due to the orthogonality constraint, $f_{N-1} - f_0 = (1 - (1/N))(1/\Delta t)$. Therefore, the bandwidth efficiency β becomes

$$\beta = \frac{\log_2 M}{\left(1 - \frac{1}{N}\right) + 2\delta\Delta t} \quad (3)$$

For orthogonal frequency spacing and strictly band-limited spectra (bandwidth Δf) with $\delta = \frac{1}{2}\Delta f = 1/2N\Delta t$, $\beta = \log_2 M$ bits/s/Hz. In reality, however, the spectra overflow this minimum bandwidth by some factor α so that $\delta = (1 + \alpha)(1/2N\Delta t)$ and the efficiency (3) becomes

$$\beta = \frac{\log_2 M}{1 + \frac{\alpha}{N}} < \log_2 M. \quad (4)$$

To obtain the highest bandwidth efficiency in an OFDM system, N must be large and α must be small.

B. Implementation of OFDM Using the Discrete Fourier Transform

The principal objections to the use of parallel systems are the complexity of the equipment required to implement the system, and the possibility of severe mutual interference among subchannels when the transmission medium distorts the signal. The equipment complexity (filters, modulators, etc.) can be greatly reduced by eliminating any pulse shaping, and by using the discrete Fourier transform (DFT) to implement the modulation processes, as shown in [7], [8]. There it is shown that a multitone data signal is effectively the Fourier transform of the original data stream, and that a bank of coherent demodulators is effectively an inverse Fourier transform. This can be seen by writing (1) as

$$D(t) = \text{Re} \left[\sum_{n=0}^{N-1} d(n)e^{-j\omega n t} \right]. \quad (5)$$

Letting $t = m\Delta t$, the resulting sampled sequence $D(m)$ is seen as the real part of the DFT of the sequence $d(n)$.¹ The act of truncating the signal to the interval $(0, N\Delta t)$ imposes a sinc frequency response on each subchannel with zeros at multiples of $1/T$. This spectral shape has large sidelobes, and gives rise to significant interchannel interference in the presence of multipath. This point will be discussed in more detail in Section III.

¹ It is convenient in this paper to think of $d(n)$ as being in the frequency domain and $D(m)$ as being in the time domain, contrary to the usual engineering interpretation [8].

Further reductions in complexity are possible by using the fast Fourier transform (FFT) algorithm to implement the DFT when N is large.

C. Pilot-Based Correction

If the transmission channel is distortionless, the orthogonality of the subcarriers allows the transmitted signals to be received without error at the receiver. Consider the system in Fig. 2 with the block of data represented by the sequence of N complex numbers $\{d(0), d(1), \dots, d(N-1)\}$. These complex numbers are generated by the data encoder from a binary data sequence. A DFT is performed on this block of data, giving the transmitted symbols²

$$D(m) = \text{DFT} \{d(n)\} = \sum_{n=0}^{N-1} d(n)e^{-j(2\pi/N)nm}. \quad (6)$$

Notice that this is a sampled version of (5) where the complex notation has been retained. All future analyses will be done in the complex domain. Under the assumption of a distortionless channel, the received data sequence (the output of the inverse DFT) will be exactly the transmitted sequence due to the orthogonality of the subcarrier tones (exponentials).

If the transmission channel distorts the signal, this orthogonality is impaired. In a flat Rayleigh fading environment (i.e., the environment is not frequency selective), the effects of the Rayleigh channel can be represented as a multiplicative noise process on the transmitted signal. This multiplicative process is characterized by a complex fading envelope with samples $Z(m) = A(m)e^{j\theta(m)}$ where the $A(m)$ are samples from a Rayleigh distribution and the $\theta(m)$ are samples from a uniform distribution [1]. These samples multiply the sequence of (6) to give

$$R(m) = Z(m)D(m). \quad (7)$$

The output data sequence $\hat{d}(k)$ is the inverse DFT of (7),

$$\begin{aligned} \hat{d}(k) &= \frac{1}{N} \sum_{m=0}^{N-1} Z(m)D(m)e^{j(2\pi/N)km} \\ &= \sum_{n=0}^{N-1} d(n) \left[\frac{1}{N} \sum_{m=0}^{N-1} Z(m)e^{j(2\pi/N)m(k-n)} \right] \\ &= \sum_{n=0}^{N-1} d(n)z(k-n) \end{aligned} \quad (8)$$

² Throughout this paper, all indexes will be assumed to belong to the set $\{0, 1, 2, \dots, N-1\}$.

where $z(n)$ is the inverse DFT of $Z(m)$. It can be seen from (8) that there is a complex-weighted averaging of the samples of the complex fading envelope. If $Z(m) = 1$ for all m (the distortionless channel), $z(k-n)$ is simply the Kronecker delta function δ_{kn} and $\hat{d}(k) = d(k)$. In the presence of fading, $z(k-n) \neq \delta_{kn}$ and

$$\hat{d}(k) = d(k)z(0) + \sum_{\substack{n=0 \\ n \neq k}}^{N-1} d(n)z(k-n). \quad (9)$$

The second term on the right represents the interchannel (intersymbol) interference caused by the loss of orthogonality. Without correction for the fading, the output sequence is corrupted by intersymbol interference *even if there is no cochannel interferer*.

Pilot-based correction provides an amplitude and phase reference which can be used to counteract the unwanted effects of multipath propagation. Similar considerations have been analyzed for single-sideband mobile radio systems [14], [15]. Coherent detection, by definition, requires a phase reference; however, gain correction is also needed in an OFDM system in a fading environment to remove intersymbol interference. If phase and gain correction is employed in the absence of cochannel interference, it is easily shown, in (9), that $\hat{d}(k) = d(k)$.

In a cellular mobile system, the dominant transmission impairment often comes from other users using the same carrier frequency. It is assumed here that the desired signal and a *single* undesired cochannel interferer are received simultaneously, and that both are digital signals modulated by different data sequences with identical signaling rates. It is also assumed that they are subject to mutually independent Rayleigh fading.

When a cochannel interferer is present in the received signal, it is not advantageous to do unlimited gain correction, due to the possibility of enhancing the energy of the interferer during deep fades of the desired signal. The detrimental effects of unlimited gain correction in the presence of a cochannel interferer can be seen as follows. Let $D(m)$ be the desired transmitted signal sequence and let $I(m)$ be the corresponding cochannel interferer sequence. With $Z_d(m) = A_d(m)e^{j\theta_d(m)}$ and $Z_i(m) = A_i(m)e^{j\theta_i(m)}$ the desired and interferer complex fading sequences, respectively, the sequence present at the receiver can be represented as

$$R(m) = Z_d(m)D(m) + \sqrt{\gamma}Z_i(m)I(m) \quad (10)$$

where γ is the interference-to-signal power ratio (SIR^{-1}). $R(m)$ is corrected by a complex correction sequence $Z_c(m) = Z_p(m)$, the complex pilot fading envelope, giving

$$\hat{D}(m) = \frac{R(m)}{Z_c(m)} = \frac{Z_d(m)}{Z_p(m)} D(m) + \sqrt{\gamma} \frac{Z_i(m)}{Z_p(m)} I(m). \quad (11)$$

Taking the inverse DFT of (11), the received data sequence becomes

$$\hat{d}(k) = \sum_{n=0}^{N-1} d(n)z(k-n) + \sqrt{\gamma} \sum_{m=0}^{N-1} \frac{1}{N} \frac{Z_i(m)}{Z_p(m)} I(m) e^{j(2\pi/N)mk} \quad (12)$$

where

$$z(k-n) = \frac{1}{N} \sum_{m=0}^{N-1} \frac{Z_d(m)}{Z_p(m)} e^{j(2\pi/N)m(k-n)}.$$

If unlimited gain and phase correction is used [i.e., $Z_p(m) = Z_d(m)$], $z(k-n) = \delta_{kn}$, there is no intersymbol interference, and (12) becomes

$$\hat{d}(k) = d(k) + \sqrt{\gamma} \frac{1}{N} \sum_{m=0}^{N-1} I(m) \frac{Z_i(m)}{Z_d(m)} e^{j(2\pi/N)mk}. \quad (13)$$

The only distortion is caused by the cochannel interferer. However, since $Z_i(m)$ and $Z_d(m)$ are statistically independent, the desired signal may be in a fade when the interferer is not, and unlimited gain correction may boost the interferer average energy above that of the desired signal.

One alternative to unlimited gain and phase correction is to have a limit on the gain correction, so as not to follow the desired signal into deep fades [1]. This is done at the expense of increased intersymbol interference, due to imperfect correction of the desired signal. In this situation, the correction signal is of the form

$$Z_c(m) = \begin{cases} A_d(m)e^{j\theta_d(m)} & \text{when } A_d(m) > \epsilon \\ \epsilon e^{j\theta_d(m)} & \text{when } A_d(m) \leq \epsilon \end{cases} \quad (14)$$

where ϵ is the gain limit and is defined relative to the average value of the local field strength. Therefore, in (12), $z(k-n) \neq \delta_{kn}$, resulting in intersymbol interference. Consequently, there is a tradeoff between increasing the intersymbol interference and boosting the cochannel interference energy.

Another alternative is to develop an optimum gain correction factor which takes both distortion effects into account. An optimum gain correction factor $F(m)$ has been derived by minimizing the mean-square distortion between $D(m)$ and $\hat{D}(m)$. The derivation of $F(m)$ has been omitted for the sake of brevity. The correction sequence then becomes

$$Z_c(m) = Z_p(m)F(m) = Z_d(m) \left[1 + \gamma \left(\frac{A_i(m)}{A_d(m)} \right)^2 \right]. \quad (15)$$

This correction procedure would be more difficult to implement than the gain limiting procedure described above.

In addition to the impairments caused by intersymbol and cochannel interference, frequency-selective fading may also be present. This phenomenon causes a decorrelation of the received signal envelopes at different frequencies, lessening the effectiveness of the pilot-correction procedure, since a data point which is being corrected may be decorrelated from the corresponding pilot complex fading envelope.

Finally, one of the major advantages of the OFDM technique is its ability to "average" out impairments, making the bursty Rayleigh channel appear much less bursty. The extent to which this averaging approaches a Gaussian channel depends on the correlation between samples of the complex fading envelope. It can be seen that as N increases, more independent fades are averaged. This enables burst errors to be randomized and thereby aids in bit error correction. This property will be more evident in the simulation results, which indicate that the curves for the bit error rate fall between the linear Rayleigh channel curves and the exponential Gaussian channel curves. For large N and high vehicle speeds, the bit error curve approaches that for a Gaussian channel.

D. Distortion Analyses

Several mechanisms contribute to the overall distortion of the desired signal. In this section, emphasis is on the contributions due to gain limiting, evident in increased intersymbol interference, and due to cochannel interference. The distor-

tion resulting from decorrelation of the pilot due to frequency-selective fading or due to interference on the pilot is considered in Section II-F.

First, consider the case of gain-limited correction, where the amplitude correction is bounded to follow fades only as deep as ϵ . Assume that the random processes which produce the random sequences are ergodic, thereby permitting the equivalence of time and ensemble averages. The pilot complex fading envelope at a particular instant in time is $Z_p(m) = Z_d(m)$ and the correction sequence is

$$Z_c(m) = \max(A_d(m), \epsilon) e^{j\theta_d(m)}. \quad (16)$$

The corrected output samples become

$$\begin{aligned} \hat{D}(m) &= \frac{R(m)}{Z_c(m)} = D(m) \frac{Z_d(m)}{Z_c(m)} + \sqrt{\gamma} I(m) \frac{Z_i(m)}{Z_c(m)} \\ &= D(m) A_d(m) \min\left(\frac{1}{A_d(m)}, \frac{1}{\epsilon}\right) \\ &\quad + \sqrt{\gamma} I(m) A_i(m) e^{j(\theta_i(m) - \theta_d(m))} \\ &\quad \cdot \min\left(\frac{1}{A_d(m)}, \frac{1}{\epsilon}\right). \end{aligned} \quad (17)$$

The signal-to-distortion ratio (SDR) can be defined as in [14],

$$\text{SDR} = \frac{|\overline{D(m)}|^2}{|\overline{\hat{D}(m)} - \overline{D(m)}|^2} \quad (18)$$

where \bar{X} denotes a time average of X . Assuming $|\overline{D(m)}|^2 \approx |\overline{I(m)}|^2 = 1$, the denominator in (18) reduces to

$$\begin{aligned} &\frac{|\overline{\hat{D}(m)} - \overline{D(m)}|^2}{|\overline{D(m)}|^2} \\ &= A_d^2(m) \min^2\left(\frac{1}{A_d(m)}, \frac{1}{\epsilon}\right) \\ &\quad + \gamma A_i^2(m) \min^2\left(\frac{1}{A_d(m)}, \frac{1}{\epsilon}\right). \end{aligned} \quad (19)$$

Assuming time averages can be replaced by expected values and assuming $A_d(m)$ and $A_i(m)$ are statistically independent and Rayleigh distributed, (18) becomes, after some manipulations,

$$\begin{aligned} \text{SDR} &= \left\{ \left(\frac{\text{SIR} + 1}{\text{SIR}} \right) \frac{1}{\epsilon^2} [1 - e^{-\epsilon^2}] + 1 - \frac{\sqrt{\pi}}{\epsilon} \text{erf}(\epsilon) \right. \\ &\quad \left. + \frac{E_1(\epsilon^2)}{\text{SIR}} \right\}^{-1} \end{aligned} \quad (20)$$

where $E_1(x) = -[\Psi + \ln(x) + (\sum_{n=1}^{\infty} (-1)^n x^n / (n n!))]$ and Ψ is Euler's constant ($\approx 0.57721566 \dots$). The SDR in (20) is plotted in Fig. 3 for several values of SIR. Obviously, if $\text{SIR} = \infty$ (no cochannel interference), the results reduce to that in [14] and no gain limit should be used. However, for $\text{SIR} < \infty$ the curves clearly indicate the tradeoff between intersymbol interference, caused by gain limiting, and boosting of the cochannel interference average energy, caused by unlimited gain correction. If unlimited gain correction is used, $\text{SDR} = -\infty$, indicating that the interferer completely distorts the desired sig-

Fig. 3. Signal-to-distortion ratio for a flat Rayleigh fading environment when gain-limited correction is used.

Fig. 4. Signal-to-distortion ratio for a flat Rayleigh fading environment when the optimum gain correction factor is used.

nal. Notice, there is a definite maximum which is fairly flat. Although SDR as defined here is an analog transmission quality measure, it does indicate the degree to which intersymbol interference, caused by imperfect gain correction, and cochannel interference are problems. These factors are critically important in digital transmission. The SDR also clearly shows the tradeoffs which must be made when choosing the appropriate gain limit. This, in turn, directly affects the bit error rate (BER), as shown in the next section.

Similar results can be derived for optimum gain correction, as in (15), and the SDR can be shown to be

$$\text{SDR} = \left[\left(\frac{1}{\text{SIR} - 1} \right) \left[\frac{\text{SIR}}{\text{SIR} - 1} \ln(\text{SIR}) - 1 \right] \right]^{-1} \quad (21)$$

which is plotted versus SIR in Fig. 4. This curve indicates the best performance for a given SIR. Notice, by comparing Figs. 3 and 4, that using gain-limited correction does not sacrifice much if the gain limit is in the vicinity of the maximum. Both of these results could be used as an aid in determining the appropriate level for gain limiting for a given SIR.

E. Simulation Results

Initial simulations were performed assuming flat Rayleigh fading. In these simulations, it was also assumed that the pilots could be recovered perfectly; that is, there is no interference or distortion on the pilots. A symbol rate and channel bandwidth of 7.5 kHz³ were used and the BER was determined for several values of SIR (100 000 bits were used in the simulation to provide statistical significance). Based on this choice for the bandwidth, the maximum bit rate is $7.5 \log_2 M$ kbits/s. Several parameters were varied in this initial investigation, the most important being N , the number of subchannels, and v , the vehicle speed. Both quantities are very important factors in determining the ability of this system to effectively randomize the burst errors created by the Rayleigh fading. The fading rate is directly proportional to the vehicle speed. In particular, at a carrier frequency of 850 MHz, independent fades are about 7 in apart, giving a fade every 6.6 ms at 60 mph. Therefore, for a given value of N , higher vehicle speeds should result in better performance because more fades are included in the averaging process. Similarly, for a given vehicle speed, if N is large, the total signaling interval is also large and more fades are again used in the averaging process.

The results shown in Fig. 5, where quadrature phase shift keying (QPSK) has been employed, indicate the improvement possible if OFDM is used with gain correction under the assumptions of ideal pilot recovery and a flat Rayleigh fading environment. Results for both optimum gain correction, as in (15), and gain-limited correction, as in (14), are given. These results clearly indicate the effects of vehicle speed and the number of subchannels. At a carrier frequency of 850 MHz and with a vehicle speed of 60 mph, with gain-limited correction, improvements in SIR of 6-7 dB⁴ have been obtained using 512 subchannels ($T = 68$ ms). This is in comparison to a flat Rayleigh channel using coherent detection ($N = 1$) with QPSK. A reduction in speed to 30 mph results in a loss in performance of less than 1 dB. A reduction of N to 128 subchannels ($T = 17$ ms) results in an additional 2 dB loss, because fewer independent fades are included in the averaging process. For the cases where gain-limited correction is used, the BER curves shown are for the "best" absolute gain limit. If the optimum gain correction factor can be determined, an additional improvement of 1 dB can be obtained. The sensitivity of the BER on the gain limit, shown in Fig. 6, indicates that adaptive gain limiting, or some "intelligent" guess at the gain limit based on the distortion curves, may be required.

F. Effects of Frequency-Selective Fading

When good correlation exists between the fading statistics of the pilot tone and those of the fading information signal, almost total suppression of the unwanted amplitude and phase fluctuations is possible. The simulation results given in Section II-E were obtained under the assumption that the fading on the pilot and the desired signal were totally correlated. This is a valid consideration when there is no interference on the pilot and when the fading is not frequency selective.

In general, however, the mobile environment is frequency selective, due to the existence of a spread in arrival times of the various multipath components. In this case, the correlation in phase and amplitude between two pilots separated in frequency is high for small frequency separation, and falls essentially to zero as the separation substantially exceeds the correlation bandwidth [1]. The gain correction process, as will be seen, requires a high degree of correlation between the phase and

³ Such a channel allows a factor of 4 improvement in spectral efficiency over the current 30 kHz cellular mobile telephone service channel.

⁴ All comparisons in this paper will be made at a BER level of 10^{-2} .

amplitude variations of the pilot and that of the phase and amplitude variations imposed on the data.

A simple way to estimate the effects of a delay spread environment is to compute the equivalent decorrelation between the pilot and the data caused by the frequency-selective fading (for example, see [12]). These calculations depend on the model used to describe the dispersive channel. In the simulations, the delay spread channel is simply modeled as a two-impulse channel response with equal-amplitude signal and echo separated by some time Δ . As in [2, sect. 9.8], an approximation model will be assumed for the delay distribution. In this model, the probability density function of the delay is represented as two equal-amplitude, equally likely impulses separated by some delay Δ . This is the model which was employed in the simulation and is a sufficient approximation for $s < \pi/2$. The rms delay spread in this case is simply $\Delta/2$. The corresponding complex correlation coefficient can be shown to be

$$\rho(s, \tau, \sigma) \approx \frac{J_0(\omega_m \tau)}{\sqrt{2}} [1 + \cos(s\Delta)]^{1/2} \quad (22)$$

where s is the frequency separation in rad/s, τ is the separation in time between two samples, and ω_m is the maximum Doppler shift in rad/s. Letting $\tau = 0$ (without loss of generality)

$$\rho(s, \sigma) = \frac{1}{\sqrt{2}} [1 + \cos(s\Delta)]^{1/2}. \quad (23)$$

The coherence bandwidth, defined as the frequency separation when the envelope correlation (ρ^2) is 0.5, is easily computed to be $1/\Delta$. According to published data for New York City [16], the rms delay spread is usually less than $3 \mu\text{s}$ ($\Delta = 6 \mu\text{s}$). However, other measurements in Newark [17] suggest that values of Δ as high as $50 \mu\text{s}$ are possible. Values of $\Delta = 25 \mu\text{s}$ were found to occur often enough and with sufficient repeatability in Newark to be regarded seriously. The usefulness of the OFDM technique has been illustrated for a flat Rayleigh fading environment. It remains to show how much the system degrades in a delay spread environment where the pilots and the data become decorrelated.

In the simulation, a bound on the effects of delay spread has been obtained by appropriately decorrelating the pilot fading sequence and the fading data sequence. At a specific instant in time, the correlation between the complex fading envelope of the pilot, $Z_p(m)$, and the complex fading envelope of the data, $Z_d(m)$, is some value $\rho < 1$. It is easily shown that this will be true if the pilot complex fading envelope is chosen as

$$Z_p(m) = \rho Z_d(m) + \sqrt{1 - \rho^2} Z_x(m) \quad (24)$$

where $Z_x(m)$ is statistically independent from $Z_d(m)$. In the previous section, ρ was assumed to be unity. Obviously, this process causes additional distortion. Using limited gain correction, it can be shown that in a frequency-selective environment the SDR is

$$\text{SDR} = \left[\left(\frac{\text{SIR} + 1}{\text{SIR}} \right) \frac{1}{\epsilon^2} (1 - e^{-\epsilon^2}) + 1 - \frac{\rho\sqrt{\pi} \cos \phi}{\epsilon} \text{erf}(\epsilon) + \left(1 - \rho^2 + \frac{1}{\text{SIR}} \right) E_1(\epsilon^2) \right]^{-1} \quad (25)$$

where $\phi = \arctan[-s\sigma]$. This reduces to (20) for $\rho = 1$ and reduces to results in [14] when $\text{SIR} = \infty$ and $\phi = 0$.

Simulation results have been obtained assuming $\Delta = 50 \mu\text{s}$

Fig. 7. Simulation results in a frequency-selective environment (QPSK, $f_s = 7.5 \text{ kHz}$, $N = 512$, $v = 60 \text{ mph}$, gain-limited correction).

(a particularly bad case measured in Newark). This value has been chosen to determine what degradations occur in an approximately worst-case dispersive environment. Frequency separations between the pilot and the data of 500 Hz and 1 kHz have been used. The results are shown in Fig. 7 and indicate that, for severe frequency-selective fading, a loss of 5 or 6 dB in BER is obtained over the flat fading case for 1 kHz separation, and less than 2 dB for 500 Hz separation. Similar degradations occur when there is interference on the pilot, either from the data spreading into the pilot due to the Doppler shift induced by the motion of the mobile, or by a cochannel pilot. The interference from a cochannel pilot decorrelates the received pilot and data signal envelopes. Thus, cochannel pilot interference induces correction distortion in a manner very similar to that induced by operating in a high delay spread environment. Obviously, in a practical implementation of this modem, some techniques must be devised to overcome the detrimental effects of delay spread and pilot interference. These will be treated in the next section.

III. PRACTICAL CONSIDERATIONS

A. Problems in Pilot Retrieval

In a practical OFDM system, a method for accurately correcting the data is required, which in turn requires a method for reliably retrieving the pilot signals. In addition, the complex fading envelope of the pilot signal must be highly correlated with the complex fading envelope of the data. A pilot signal, located somewhere within the transmission band, must be sent with the data. This pilot will be distorted in transmission by cochannel interference, by adjacent data symbols spreading into the pilot due to the motion of the vehicle, by filtering processes, and by the decorrelation between the pilot fading envelope and the signal fading envelope caused by

a frequency-selective environment. Techniques will be presented which alleviate these distortions.

B. Techniques for Reliable Pilot Retrieval

When there is adequate separation between the pilot tone and its neighboring information components, it is possible to separate the spread pilot from the spread signal components, without fear of overlap, by suitable filtering in the receiver. Assuming a top vehicle speed of 60 mph and transmission at 850 MHz, each subchannel spreads ± 80 Hz (due to the Doppler shift). Therefore, a 200 Hz spacing between the pilot frequency and the nearest data subcarrier provides more than enough protection against overlap. However, due to the use of the DFT, each subchannel possesses a $\sin x/x$ spectrum which has fairly large sidelobes, and which may cause problems if the orthogonality of the subcarriers is impaired. The sidelobes can be reduced either by filtering the individual subchannels before transmission (for example, see [6]), or by extending the frame of data in time and by requiring gradual rather than abrupt rollofs of the transmitted waveform [8]. In this paper, the latter technique is employed to avoid the complexity created by prefiltering. In particular, the data block is modulo extended in time, and then the extended sections are shaped with a raised cosine and added as shown in Fig. 8. This reduces the sidelobes but widens the main lobe. The length of the extension determines the width of the main lobe beyond that of the $\sin x/x$ spectrum.

When the effects of the data on the pilot signal have been sufficiently attenuated, cochannel pilot interference can be attacked. A frequency offset reference transmission scheme works well to minimize the effects of cochannel pilot interference. In this scheme, the slot for pilots in the total band is further divided into several slots for cochannel interferer pilots. Specifically, in this paper, three adjacent slots are made available, increasing the total pilot allocation to 1000 Hz. This technique effectively increases frequency reuse by a factor of 3.

In a frequency-selective environment, a high correlation between the complex fading envelopes of the pilot and the data must be ensured. Based on the results in Section II-F, this depends on the severity of the delay spread and on the frequency separation between the pilot and the data subcarrier. Assuming a harsh delay spread environment (for example, $\Delta = 50 \mu\text{s}$), the pilot and data must be very close in frequency (< 500 Hz) to constrain the loss due to decorrelation to 2 dB. If a 7.5 kHz channel is used, placing the pilot in the center of the band results in data symbols at the edges that are 3.75 kHz away from the pilot. This large separation causes a large degradation in BER. With smaller amounts of delay spread (for example, $5 \mu\text{s}$) this is not a problem. This large degradation can be avoided if two pilots, separated in frequency, are used and the appropriate complex correction signal is obtained by interpolation *in frequency* between these two pilots.

In general, separate amplitude (A) and phase (θ) interpolation is not appropriate. For the two-impulse channel model for delay spread which is being used here, the amplitude response is as shown in Fig. 9. It is possible for both pilot fading envelopes to be at peaks, due to the randomness of the initial position of the 7.5 kHz data window. The resulting amplitude and phase interpolation will be inadequate to follow the null in frequency caused by the fading. Interpolation separately the real (in-phase, I) and imaginary (quadrature, Q) parts of the complex fading envelopes of the pilots will enable such a correction to occur. Simulation results, presented in Fig. 12, indicate that I - Q interpolation gives 8 dB improvement over A - θ interpolation for $50 \mu\text{s}$ delay spread. Similar results will be obtained for other models for the dispersive channel. The technique depends only on nulls occurring in the channel frequency response.

Finally, the design of a mobile telephone system must also

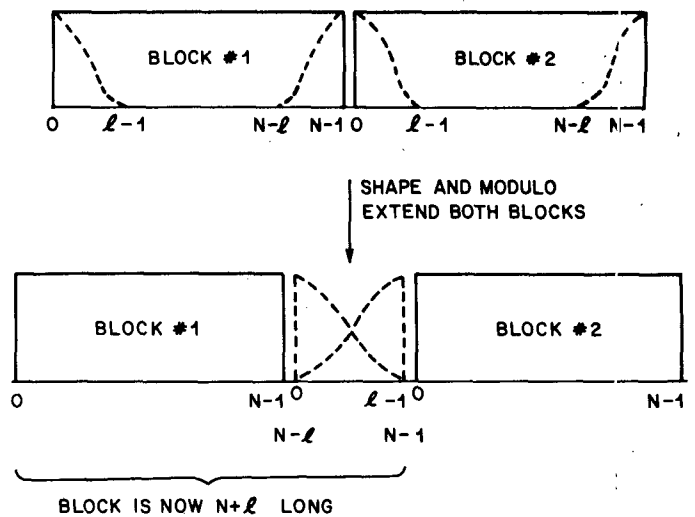

Fig. 8. Modulo extension and shaping of data block to reduce inter-channel interference caused by impairment of orthogonality.

Fig. 9. Possible amplitude response for two-impulse channel model for delay spread, $\Delta = 50 \mu\text{s}$, $A(\omega) = 2 |\cos \omega \Delta / 2|$.

include measures to limit adjacent channel interference. This is accomplished by leaving 250 Hz gaps at each end of the band. The final data setup used in the simulations is shown in Fig. 10. The total bandwidth used by the data has now been reduced to 5 kHz.

C. Basic System Setup and Pertinent Parameters for Simulation

Simulations were performed incorporating all of the design features presented in the previous section. The pertinent system parameters were carefully selected, based on an initial assumption of a 7.5 kHz channel. T , the total signaling interval,

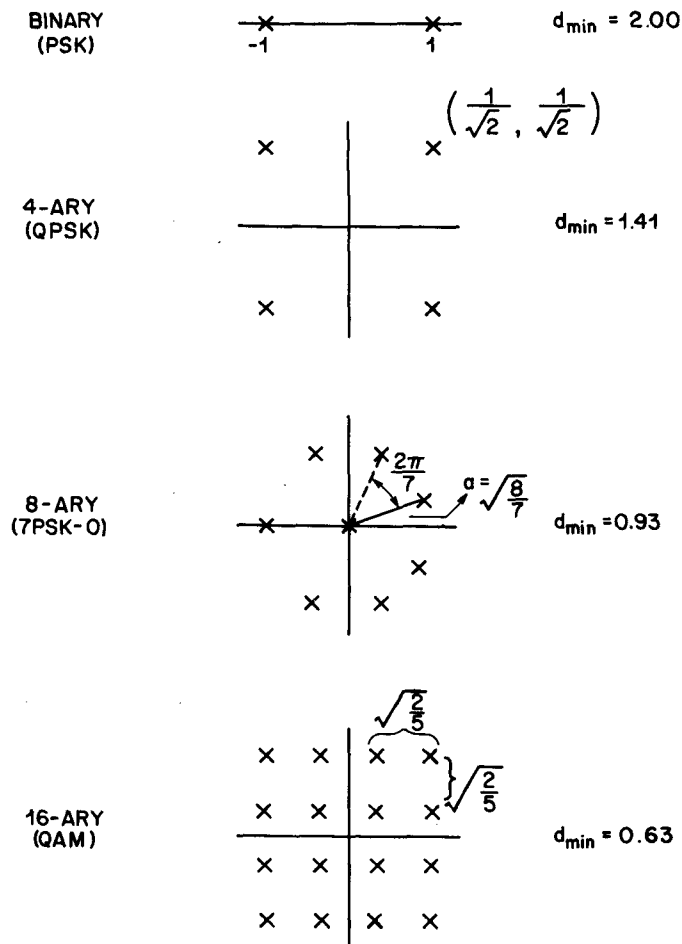

Fig. 11. Modulation formats used in simulations (average energy = 1).

should be chosen to be much greater than the average duration between fades, so that many fades are averaged in the receiver. In the previous simulation, T was 68 ms and good results were obtained. However, based on subjective opinions, a signaling interval of 68 ms was shown to result in a noticeable round trip delay for speech transmission when buffering and processing times are included. Also, by making T too large, the subchannels are closer together and the inter-channel interference due to spreading may become unacceptable. An interval on the order of 20 ms ($N = 128$) is more satisfactory. This decrease in T results in a degradation of about 2 dB in performance compared to $T = 68$ ms.

Note that the average interval between fades tends to infinity as the speed of the mobile approaches zero. Therefore, T must be very large at low speeds to obtain any averaging. A solution to this problem is to make the vehicles always appear to move at some substantial speed, such as 30 mph. One way this can be done is by forcing an antenna to oscillate when the vehicle is moving at low speeds, as in [18].

Assuming an initial sample rate of 7.5 kHz and letting $N = 128$ gives $T = 17.06$ ms and $\Delta f = 58.59$ Hz. Assuming a total interval of 20 ms, these parameters allow 2.93 ms of extension. Sacrificing two bands of 1000 Hz each for pilot protection and 250 Hz at either end for adjacent channel interference protection leaves space for 86 data channels and a bandwidth efficiency of $\beta = 0.57 \log_2 M$ bits/s/Hz. For QPSK, this corresponds to a maximum data rate of 8.6 kbits/s.

D. Simulation Results

In this simulation, several different two-dimensional modulation formats were considered. These are shown in Fig. 11, along with the corresponding minimum distances. Results

Fig. 12. Simulation results ($N = 128$, $v = 30$ mph, $f_s = 7.5$ kHz).

were obtained for binary (BPSK), 4-ary (QPSK), 8-ary (7PSK-0), and 16-ary (QAM) modulation schemes. The 8-ary constellation used a seven-point phase shift keying pattern with an additional data point at the origin. This requires a two-step detection procedure, but gives 1.7 dB improvement in performance over conventional 8-PSK, based on comparison of the minimum distances in each constellation. These patterns could form the basis of a multimode system.

Simulation results for a flat Rayleigh fading environment are shown in Fig. 12. Gain-limited correction has been used in the data correction process. These results are computed for a vehicle speed of 30 mph. For a vehicle speed of 60 mph, there is an improvement of 1 dB. Each pilot was also run 10 dB higher in energy than any individual data point, for additional protection of the pilots. By using the frequency offset reference technique to combat cochannel pilot interference, the total pilot-to-distortion ratio is 25 dB, a reasonable level of distortion. The pilot filters were implemented, in the simulation, as low-pass FIR filters with 100 Hz passbands. These filters added no significant distortion to the pilots. The results in Fig. 12 indicate the improvements which are attainable with this technique. Gains of 2-3 dB were obtained for OFDM-QPSK over coherent QPSK. An additional 3 dB is gained over differential QPSK (DQPSK).

Fig. 12 also indicates the BER for QPSK when there is significant delay spread. Delay spread was implemented as a statistically independent delayed echo added to the desired signal. At a BER = 10^{-2} , there is a loss of only 2 dB in SIR for $\Delta = 50 \mu s$. For $\Delta = 10 \mu s$, the loss is about 0.5 dB. The losses due to delay spread have been minimized by interpolating *in frequency* ten appropriately spaced pilots, which are then each used to correct the data sequence. The appropriate sym-

Fig. 13. Delay spread implementation and pilot correction procedure.

bolts are then chosen at the output. The correction procedure is indicated in Fig. 13 and the symbols corrected by each pilot are given in Table I.

Variations such as changing the pilot locations, changing the number and locations of the interpolated pilots, and changing the length of the time extension have a large effect on the BER. Based upon numerous trials, it has been determined that for ten interpolated pilots, the system simulation used in this section is close to an optimum.

IV. CONCLUSIONS AND FURTHER INVESTIGATIONS

In this paper, a cellular mobile radio system based on orthogonally frequency division multiplexing many low-rate subchannels into one higher rate channel was analyzed and simulated. This technique, when used with pilot-based correction, was shown to provide large improvements in BER performance in a *flat Rayleigh fading* environment. Degradations due to *severe* delay spread were kept to a minimum by frequency interpolation of two pilots. Using a frequency offset scheme for the pilots limited the effects of cochannel pilot interference. These considerations provided very good BER performance, at the expense of a decrease in the overall bandwidth efficiency. The averaging ability of the OFDM system, which makes the bursty Rayleigh channel appear nearly Gaussian, provides this large BER improvement. Additional improvements are possible if larger signaling intervals are permissible.

Other factors which also impair the orthogonality of the subcarriers, such as phase and gain hits, phase jitter, and frequency offset, have not been considered. In [13], these impairments were considered for a voice-bandwidth data modem. There it is shown that some form of frequency domain equalization can be used to alleviate the effects of these impairments.

TABLE I
DATA SYMBOLS CORRECTED BY EACH INTERPOLATED PILOT

INTERPOLATED PILOT POSITION	DATA SYMBOLS CORRECTED
8	5, 11
16	12, 21
40	38, 44
50	45, 54
60	55, 64
70	65, 74
80	75, 84
90	85, 91
113	109, 117
121	118, 123

Some alternative coding schemes for the OFDM system have been briefly considered. Two possibilities for coding in this system are analog and Ungerboeck codes. Analog codes have recently gained quite a bit of interest (for example, see [19]). One approach is to use fixed transmitted symbols to correct symbols in error. In initial trials for the OFDM system, this technique was not very effective, because the large noise term on each symbol caused by cochannel interference was enough to offset the effectiveness of the algorithm. Further study in this area may prove fruitful. Ungerboeck codes [20] map data symbols into a higher order constellation and, in a Gaussian, white noise environment, have been shown to provide as much as 3 dB coding gain without sacrificing data rate or requiring more bandwidth. These codes, although untested in a fading environment, present a possibility for our system.

ACKNOWLEDGMENT

The author would like to acknowledge gratefully N. Sollenberger and K. Leland for their helpful suggestions throughout the course of this project.
